Model in K L

A model is congthing that agent can use to predict the environments behaviour Given an state of action a model predicts the rext state of next reward stochastic -> several possible states with probability (distribution model) sample model - give only I state with highest probability > current states observe > Agent - Action A decide Next state (5') after (A) is taken is determined by the environment. But if the environment is not available this work is done by model Model car just replace environment.

## Planning in PL

Planning is any computational process that takes a mobel as input and produces or improves policy for interacting with modelled environment

Model Planning Policy

dearning is when we actually interact with the anvironment

Environment Learning > Policy

Planning uses simulated experiences generated by model Learning uses real experiences

Model based (D.P., huristic search) rely on Planning Model free (ML, TDL, etc) rely on learning

Learning
Real experience
Model free
Model hased
May be slower depending faster
On environment

In many cases, learning algorithm can be used for planning.

eg Planning & learning where everything is the same except emirronment is replaced by model

Model free vs Model based

Model hased methods work well when the model is known.

In such cases (toy problems) the model

In such cases (toy problems) the model and environment are the same

But in real life cases if the knowledge about the exact environment is not known then model  $\neq$  env.

This may be due to incorrect assumptions

(D.P.) So when P(s|s,a) & P(s,a) are estimates and not true values, model \( \pm \) env.

Also in some applications like recommendation systems and financial markets, the environment may change over time.

In such cases, the model used is just an estimate or approximation of the environment.

Model free methods on other hand learn directly from the environment

Model may be incorrect because -

© Environment is stochastic and only a limited amount of experience is available

© Model has learned using a function approximator that failed to generalize

3 Environment has changed and new behaviour has not been observed yet.

Planning Vs learning Input

Current state Agent output Agent is a black box with input S output A. I is used for learning S & of need to be supplied by environment or someone else In Learning FL -> Action to be taken A Senvironment Current state In Planning PL -> Action to be taken A Model Current state A model is used to simulate the environment Note -> for off policy historical learning There is no environment, just dataset Pataset Model (a(A) is used only to normalize the reward lie importance sampling Action has already been predecided by b

Pirect & Indirect FL \* what we can do with real experience 1) Model learning - Improve model to match it with the environment (to cope environment changes) ② Direct R∠ → Improve Value functions and policy from environment (learning) 3 Indirect FL → Improve Value function and policy from model (Planning) Direct methods are not affected by bias in model design But real world interactions may be costly With a model, agent can "Imagine" ie. simulate transitions between states without needing to interact directly with the environment If all these 3 methods are combined, then there will be increase in efficiency Agent will learn from real environment as well as simulated models. So the agent can update policy multiple times on single real update - faster learning

Vyna - 9 Simple Architecture integrating major functions of an online planning agent It combines model free of model based techniques. Model Environmen ? (Experience) learning Take Action & learn from real Experience step 1) Agent selects action based on TI ( E-greedy) current state is the state current state is the last construmed by and Not learning phase planning phase Take action observe reward of new state lepolate Thesing & learning - Given by Environment Max O(s,a) based on Previous Q step 2) llpdate the Model record S'& R to update P(S,S,a) (a is action taken) step 3) Simulate experience (Planning) Agent generates number of simulated experiences
using Model
for each simulated experience, update Q-value
as if it were a real experience This step allows the agent to make rapid progress by learning from hypothetical experiences without actually interacting with the environment A R from Model

Si from previous Q Current state (\*) randomly Randomly selected from past state action poirs (5, 9) Report Planning N times Then go back to step ! Note -> The current state for learning remains same as it was after the most recent real (environmental) experience, not the state from any of the planning steps. The planning steps only modify the Qualues and not agents current state 54 experiame Sz 55 Neal experience

## Pyna Q +

Designed to improve exploration for Non stationary environments where &, P changes over time

Introduces exploration borns to agent to sevisit the states and actions that it has not visited recently in simulated experience

Model keeps trank of each state - action pair of how many time steps have elapsed since it was last tried in a real interaction.

Special bonus is assigned  $s \rightarrow s + k \sqrt{7}$ Mas cost for revisit, but transition not tried worth it for changing environment for Trewards in seal world eg Grid world barries moves

In such cases revisiting states is helpful

## Prioritized Surceping

Instead of updating random state action poins during planning prioritized succepting selectively updates only those pairs with highest potential for learning.

These state action paies are prioritized based on how much their & values could change

By focusing only on these high impact updates, prioritized sweeping achieves faster learning with fewer updates.

70 error -> | 8 + 8 max 9(s, a)-8(s, a) |

estimated goodness goodness

high 7.D. error means updating the Qualue could significantly improve the agents knowledge

Once a (s,a) is visited,

Calculate 7D error for (5,9) Calculate 7D error for Predessors

Add all to priority queue with priority = TD error (Thresholding can be done)

In planning phase instead of randomly selecting actions, take actions from priority queue

For each predenors, when they come in planning phase for explate, calculate the Q of their predenors too.

A predessor state are the states that could transition into the current state under some action.

Priority sweeping has been found to dramatically increase the speed of convergence.
